We investigate the superfluid properties of a dipolar Bose-Einstein condensate (BEC) in a fully three-dimensional trap. Specifically, we estimate a superfluid critical velocity for this system by applying the Landau criterion to its discrete quasiparticle spectrum. We test this critical velocity by direct numerical simulation of condensate depletion as a blue-detuned laser moves through the condensate. In both cases, the presence of the roton in the spectrum serves to lower the critical velocity beyond a critical particle number. Since the shape of the dispersion, and hence the roton minimum, is tunable as a function of particle number, we thereby propose an experiment that can simultaneously measure the Landau critical velocity of a dipolar BEC and demonstrate the presence of the roton in this system.

Liquid $^4$He was the first experimentally accessible system to exhibit dissipationless flow at low temperature, i.e., to demonstrate superfluidity in a quantum system. Landau famously explained this phenomenon by identifying a critical velocity $v_L$ below which elementary excitations in the fluid could not be excited while conserving energy and momentum [1]. Because of this connection to the spectrum $\omega(k)$ of elementary excitations, the Landau critical velocity can be expressed as

$$v_L = \min \left[ \frac{\omega(k)}{k} \right]. \quad (1)$$

Remarkably, the Landau critical velocity $v_L$ does not coincide with the speed of sound in liquid helium, but is smaller due to the existence of an anomalously low-energy roton mode at wave vector $k \sim \AA^{-1}$. This critical velocity was ultimately verified in experiments of ion drift velocity in liquid $^4$He [2].

More recently, a new class of superfluids has been produced in the form of Bose-Einstein condensates (BECs) of ultracold atomic gases. These gases have a distinct advantage over liquid helium in that they are dilute and hence easily characterized in terms of microscopic interactions. In particular, their critical velocity is nominally given by the speed of sound in the center of the gas, which can be easily calculated from the density and the $s$-wave scattering length of the constituent atoms. Early experiments at MIT sought to measure $v_L$ in a BEC of sodium atoms by stirring the condensate with a blue-detuned laser [3,4]. However, these experiments measured a critical velocity for spinning off vortices rather than the true Landau critical velocity. This is a generic feature of such experiments in which the size of the object (in this case, the blue-detuned laser) is large compared to the healing length of the gas [5–8].

Still more recently, atomic BECs have been created whose constituent atoms possess magnetic dipole moments large enough to influence the condensate [9,10]. These gases present a middle ground between atomic BECs and dense superfluid helium. Namely, the dipolar BEC (DBEC) is dilute enough to be understood in detail, yet its spectrum may exhibit roton features in prolate traps, like those of liquid He [11]. The characteristic momentum of such a roton is set by the geometry of the trap in which it is held, whereas its energy is controlled by the density of dipoles, as well as the magnitude of the dipole moment [10]. Thus, by Eq. (1), the Landau critical velocity is completely under the control of the experimentalist. In contrast, $v_L$ in $^4$He can be only weakly modified by changing the pressure of the liquid [12]. Thus, the DBEC provides an unprecedented opportunity to explore the fundamental relationship between the roton dispersion and superfluidity.

In this Letter we model an experiment on a DBEC similar to the MIT experiments. We consider a blue-detuned laser sweeping through a DBEC at a constant velocity, then compute the resulting condensate depletion due to the excitation of quasiparticles. We find an onset of depletion at a critical velocity that is near the Landau critical velocity at low densities. At higher densities, where the roton determines $v_L$, the critical velocity is a decreasing function of density. Moreover, the simulations show a critical velocity that is somewhat smaller than $v_L$ at higher densities. We attribute this to the role that the roton plays in the mechanical stability of a DBEC.

An ultracold, dilute DBEC containing $N$ atoms is well modeled within mean-field theory by the time-dependent nonlocal Gross-Pitaevskii equation (GPE),

$$i\hbar \frac{\partial \Psi(r, t)}{\partial t} = \left\{ -\frac{\hbar^2}{2M} \nabla^2 + U(r) + (N - 1) \right\} \times \int d\mathbf{r}' V(|\mathbf{r} - \mathbf{r}'|)|\Psi(\mathbf{r}', t)|^2\Psi(r, t), \quad (2)$$

where $\Psi(r, t)$ is the condensate wave function, normalized to unity; and $U(r) = \frac{1}{2}Ma^2(\rho^2 + \lambda^2z^2)$ is the cylindrically symmetric harmonic trap potential with aspect ratio $\lambda = \omega_z/\omega_\rho$ where $\omega_z$ and $\omega_\rho$ are the axial and radial trap frequencies, respectively. The two-body interaction potent-
tial for polarized dipoles with dipole moment $d$ and zero scattering length is \cite{13} $V(r - r') = d^2 1/\sqrt{|r - r'|}$, where $\theta$ is the angle between $r - r'$ and the polarization axis. We choose the polarization axis to be the trap axis $\hat{z}$ so that the system is cylindrically symmetric. To characterize the strength of the dipole-dipole interaction (DDI), we define the dimensionless quantity $D = (N - 1) \frac{\hbar d^2}{2 \omega_p}$ where $\omega_p = \sqrt{\hbar/M \omega_p}$ is the radial harmonic oscillator length of the trap. The quantity $D$ then characterizes either the density of the gas or the dipole moments of the atoms in the gas.

We perturb this DBEC with a blue-detuned laser moving at constant velocity $v$, which amounts to adding a potential

$$U_{\text{las}}(r, t) = \frac{U_0}{\sigma} \exp \left( -\frac{2[\sigma^2 + (y - y_{\text{obs}}(t))^2]}{\sigma \bar{w}_0^2} \right) \tag{3}$$

where $\sigma = 1 + (z/z_0)^2$, $z_0 = \pi \bar{w}_0^2 / \lambda_{\text{las}}$ is the Raleigh length, $\bar{w}_0$ is the beam waist of the laser, $\lambda_{\text{las}}$ is the wavelength of the laser, $y_{\text{obs}}(t) = \Theta(t - t_0)[v(t - t_0)]$ describes the motion of the laser in the $y$ direction and $\Theta(t)$ is the Heaviside step function. This potential describes a laser that is stationary until $t \leq t_0$, at which time it moves to the edge with velocity $\vec{v} = v \hat{y}$.

The effect of this blue-detuned laser on a DBEC is shown in Fig. 1 for a DBEC with aspect ratio $\lambda = 20$, $D = 124$, and a laser with $\bar{w}_0 = 0.4 a_p$ and $U_0 = 2 \omega_p$ where the chemical potential of the unperturbed condensate is $\mu = 26.3 \hbar \omega_p$. We estimate the Landau critical velocity for this system to be $v_L \sim 1.5 a_p \omega_p$. For a laser velocity less than this [Fig. 1(a)], the condensate is completely unaffected whereas for a velocity larger than this [Fig. 1(b)], quasi-particles are excited and the fluid would produce a net force on the moving laser.

To determine the Landau critical velocity $v_L$, we calculate the condensate’s quasi-particle spectrum by solving the Bogoliubov–de Gennes (BdG) equations. Because of cylindrical symmetry of the system, the condensate plus BdG quasi-particles can be written as

$$\psi(r, t) \rightarrow \psi_0(\rho, z)e^{-i\mu t} + \sum_j [c_j(t)u_j(\rho, z)e^{i(m \varphi - \omega_j t)} + c_j^*(t)v_j(\rho, z)e^{-i(m \varphi + \omega_j t)}], \tag{4}$$

where $\omega_j$ is the quasi-particle energy, $m$ is the projection of the quasi-particle momentum onto the $z$ axis and $\mu$ is the chemical potential of the ground state. Here, $\psi_0(\rho, z)$ is the stationary condensate wave function, i.e., the solution of Eq. (2) with time dependence $e^{-i\mu t}$, and is normalized to unity. The coefficients $c_j(t)$ must be sufficiently small so that the BdG equations can be derived by linearizing the GPE about them. Their time dependence describes slowly varying quasi-particle occupations (compared to $\omega_j^{-1}$) in out-of-equilibrium states.

In this formalism, the quasi-particles are characterized by their energies $\omega_j$ and $m$ quantum numbers. However, in order to apply the Landau criterion to this system, the quasi-particles must be characterized by a momentum, as well. To do this, we calculate the expectation value of the momentum, or $\langle k_p \rangle = \sqrt{\langle k_p^2 \rangle}$, of the quasi-particles. Using a Fourier-Hankel transform \cite{14}, we transform the modes into momentum space and compute the expectation value of the linear momentum of the $j$th quasiparticle in momentum-space representation,

$$\langle k_p \rangle_j = \left[ \frac{\int d\mathbf{k} k_j^2 |\tilde{u}_j(k)|^2 + |\tilde{v}_j(k)|^2}{\int d\mathbf{k} |\tilde{u}_j(k)|^2 + |\tilde{v}_j(k)|^2} \right]^{1/2}, \tag{5}$$

where we have time-averaged cross terms $\propto \cos^2 \omega_j t$ that oscillate on fast time scales \cite{15}. By associating these momenta to the excitation energies $\omega_j$, we determine a discrete dispersion relation for this system. Although the Landau criteria for superfluid critical velocity is derived for a translationally invariant fluid, we apply it to this translationally variant system to provide a hint as to where a critical velocity for quasi-particle excitations might be and to test the application of this criterion to discrete systems.

Figure 2 shows the discrete dispersion relations of a DBEC for various values of $D$. For $D = 0$ (not shown), the dispersion is given by the well-known harmonic oscillator spectrum $\omega = n_p \omega_p$ with $\langle k_p \rangle = \sqrt{n_p + 1}/a_p$ and $n_p = 0, 1, 2, \ldots$. However, as $D$ is increased, the spectrum changes to develop a phonon character at low momenta and a roton character at intermediate momenta. Indeed, for $D = 175.2$, and more so for $D = 230.0$, there are some quasi-particles that branch off from the dispersion towards lower energies and approach a momentum $\langle k_p \rangle \sim \sqrt{20}/a_p$, corresponding to the characteristic roton wavelength $\lambda_{\text{roton}} \approx 2 \pi a_z$, where $a_z = \sqrt{\hbar/M \omega_p}$ is the axial harmonic oscillator length. The modes with similar momenta but higher energy, on the upper branch of the dispersion, exist in lower-density regions of the condensate while the
Landau critical velocities for each $D$ increased, the dispersion develops a phononlike character at values of $D$ larger determined according to Eq. (1) as the slope of the shallowest smaller dispersion curve; these lines are indicated in the figure. For line through the origin that intersects a point on the dis-
nonlike modes where $m$ mode is very small compared to the total condensate tem. In any event, we find that the occupation of the Kohn breaking of superfluidity in a translationally invariant sys-
to the center of mass, which would imply the
depth. The Kohn mode moves the condens-
state [17]. The Kohn mode moves the conden-
small with our weak laser. We have deliberately remained in the perturba-
tive limit with our simulations to uncover the basic physics without the complications of large laser size. Additionally, we have checked that these lasers are not sufficient to excite vortex states in the DBEC. In practice, larger condensate depletion would be obtained from a repeated back-and-forth stirring, as was done in the MIT experiments, or from a wider, stronger laser. While such a laser may spin off vortices in the condensate, thus defining a critical

where $\Psi(r,t)$ is the numerical solution of the time-
dependent GPE with the blue-detuned laser potential. The quasiparticle occupations are then given by $n_j(t) = |c_j(t)|^2 \int dr |u_j(r')|^2 + |v_j(r')|^2$. In the simulations, the system evolves for a time $T$ after the laser has completely left the system. We average the quasiparticle occupations for a time $T$ after this, giving the average excited state occupations $\bar{n}_j = \frac{1}{T} \int_0^T dt |c_j(t)|^2$. We find that $T = 5 \omega_p^{-1}$ is sufficient to converge these averages.

Figure 3 illustrates the total quasiparticle occupation $n_{\text{tot}} = \sum_j \bar{n}_j$ as a function of laser velocity for various values of $D$ using the laser parameters $\bar{w}_0 = 0.3 a_\rho$, $z_0 = 0.7 a_\rho$, and $U_0 = 0.4 \hbar \omega_p$. For each $D$, $n_{\text{tot}}$ stays very small until, at a certain critical velocity $v_{\text{crit}}$, it begins to increase significantly. Operationally, $v_{\text{crit}}$ is determined by the intersection of linear fits below and above $v_{\text{crit}}$. Well above $v_{\text{crit}}$, the occupations decrease with velocity since the laser spends proportionally less time in the system as its velocity is increased.

Notice that the overall depletion remains small with our weak laser. We have deliberately remained in the perturbative limit with our simulations to uncover the basic physics without the complications of large laser size. Additionally, we have checked that these lasers are not sufficient to excite vortex states in the DBEC. In practice, larger condensate depletion would be obtained from a repeated back-and-forth stirring, as was done in the MIT experiments, or from a wider, stronger laser. While such a laser may spin off vortices in the condensate, thus defining a critical

In evaluating $v_{L}$ from the discrete dispersion relation, we have ignored two excitations. One is the unphysical $m = 0$ Goldstone mode. A second is the $m = 1$ Kohn mode, which has eigenvalue $\omega_1 = \hbar \omega_p$ independent of inter-
ctions, and which corresponds to transverse sloshing of the condensate [17]. The Kohn mode moves the condens-
ate’s center of mass rather than exciting quasiparticles relative to the center of mass, which would imply the breaking of superfluidity in a translationally invariant sys-
tem. In any event, we find that the occupation of the Kohn mode is very small compared to the total condensate depletion.

We now compare $v_{L}$ as determined from the discrete dispersion relation with the onset of condensate depletion due to the laser having been moved through the DBEC. To quantify the breaking of superfluidity in the simulations, we calculate the depletion of the condensate by finding the quasiparticle occupations. In practice, this is achieved by calculating the amplitudes $c_j(t)$ in Eq. (4) [18] via the orthogonality relations of the BdG modes [15], including their normalization $\int dr [u_j^*(r') u_j(r') - v_j^*(r') v_j(r')] = \delta_{jj'}$, to give

$$c_j(t) = \int dr [u_j^*(r') \Psi(r', t) - \Psi^*(r', t) v_j^*(r')] e^{i \omega_j t},$$

FIG. 3 (color online). The occupations of the quasiparticles excited from a DBEC with aspect ratio $\lambda = 20$ by a blue-
detuned laser moving with velocity $v$ (plotted on the horizontal axis) and with parameters $\bar{w}_0 = 0.3 a_\rho$, $U_0 = 0.4 \hbar \omega_p$, and $z_0 = 0.7 a_\rho$, for various values of $D$. At a critical $v$ (indicated by the arrows), the occupations increase suddenly, indicating that the laser has excited quasiparticles in the system and superfluidity has been broken.
velocity smaller than \( v_L \), the roton, for large enough \( D \), would still determine the critical velocity.

Critical velocities determined from numerical simulations are presented in Fig. 4 as a function of \( D \). Results are shown for comparatively weak \( (U_0 = 0.4\hbar\omega_p) \) and strong \( (U_0 = 2\hbar\omega_p) \) lasers. Also shown for comparison is \( v_L \) (dashed line) as determined from the discrete dispersion relations. At small \( D \), the critical velocity grows slightly as the phonon modes stiffen and the speed of sound increases. This behavior is much like that of a BEC with purely contact interactions.

At higher density, the critical velocity instead decreases, due to the decreasing energy of the roton, and this is seen in both simulation and \( v_L \). The agreement is less perfect than in the phonon regime, however, with the simulated result being lower. This is because the roton, being the collapse mechanism for DBECs in traps with larger aspect ratios, softens with increasing condensate density. The presence of the laser in the DBEC serves to increase the density of the system, softening the roton and thus decreasing the critical velocity of the condensate, just as a stationary laser leads a DBEC to instability [19]. For vanishingly small lasers, the critical velocities extracted from numerical simulation show better agreement with \( v_L \).

Finally, it is worthwhile to consider measurements of critical velocities in experimentally accessible DBECs, such as the \( ^{52}\text{Cr} \) system in Stuttgart [9]. Consider \( ^{52}\text{Cr} \) atoms whose scattering lengths have been tuned to zero in a trap with radial and axial frequencies \( \omega_p = 2\pi \times 100 \text{ Hz} \) and \( \omega_z = 2\pi \times 2000 \text{ Hz} \), respectively. This corresponds to a radial harmonic oscillator length of \( a_p = 1.391 \, \mu\text{m} \), particle numbers of \( N \sim 570D \), and critical velocities in the range of 0.11 cm/s. These circumstances suggest that it may be plausible to observe the decline of the superfluid velocity with \( D \) for \( N \approx 8.5 \times 10^8 \, ^{52}\text{Cr} \) atoms, and hence to exhibit directly the roton’s influence on superfluidity. This atom number corresponds to a maximum condensate density of \( n_{\text{max}} \approx 9.5 \times 10^{14} \text{ cm}^{-3} \), which, given the measured 3-body loss coefficient \( L_3 = 2 \times 10^{-28} \text{ cm}^6/\text{s} \) [10], should not produce significant losses over the time scales considered here. Additionally, we have checked that, for sufficiently large \( D \), the roton serves to determine \( v_L \) for \( ^{52}\text{Cr} \) DBECs with nonzero s-wave scattering lengths within the experimental uncertainty for \( ^{52}\text{Cr} \), \(-3a_0 \leq a \leq 3a_0 \) [20], which is expected because these scattering lengths are sufficiently less than \( ^{52}\text{Cr}'s \) dipole length \( d_{dd} \approx 15a_0 \) [10].
